Trade-offs

Introduction

Introduction

- The Deep Underground Neutrino Experiment (DUNE) is projected to record roughly 30 PB of liquid-argon TPC data per year [1]—far beyond the scale of previous neutrino experiments.
- DUNE's Phlex test-stand at Fermilab provides realistic hit/wire samples to prototype read-out and offline storage.
- ROOT's new RNTuple backend is a candidate for the long-term DUNE data model, promising faster compression, cluster-aware reads, and thread-safe writes.
- This study benchmarks alternative RNTuple *persistent layouts* (AOS/SOA, vertical splits, granularity levels) for realistic data products.
- Focus data products: recob::Hit (charge deposits) and recob::Wire (ROI-compressed waveforms).

Motivation

• A single DUNE far-detector module streams about 1.2 TB/s of raw data before compression [2]; naive storage could potentially overwhelm the archival budget.

 Efficient layout choice can cut file size and accelerate cluster reads needed for GPU/CPU reconstruction farms.

Problem Statement

 Which RNTuple persistent layout minimises read time, write time and on-disk footprint for DUNE Hit/Wire hierarchies?

 How does vertical splitting such as one RNTuple for all data products interact with horizontal granularities (event, spill, element) under Phlex workloads?

 How does the choice of persistent layout affect the performance of the read and write operations?

Objectives

Benchmark seven layout variants on a 1 M-event Phlex dataset (recob::Hit, recob::Wire with ROIs).

• Measure: write throughput, cold/warm read latency, compressed file size, and multi-thread scaling (1–64 threads).

Quantify trade-offs of ROI flattening, vertical split depth, and SOA vs. AOS.

Persistent Layouts

Data Layouts: AOS vs. SOA

Array of Structures (AOS)

Stores complete objects in an array.

```
struct Hit {
long long EventID;
unsigned int fChannel;
float fPeakTime;
};
// Array: [Hit1, Hit2, ...]
```

Example: Hit, Wire (per-item entries).

Structure of Arrays (SOA)

Separate arrays per field.

```
struct Hits {
vector<long long> EventID;
vector<unsigned int> fChannel;
vector<float> fPeakTime;
};
// Columns: EventID[], fChannel[
], fPeakTime[], ...
```

Example: Hits, Wires (per-event vectors).

Layout Strategies

Layout Strategies: AOS vs SOA

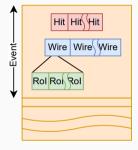

Figure 9: AOS Layout

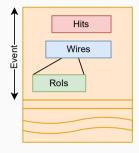

Figure 10: SOA Layout

Granularity vs. Vertical Split Matrix

Horizontal Granularity	1 NTuple (all DP)	1 NTuple / DP	1 NTuple / group
Event-wise	event_allDP()	event_perDP()	event_perGroup()
Spill-wise	$spill_allDP()$	spill_perDP()	spill_perGroup()
Top-object-wise	_	<pre>topObject_perDP()</pre>	<pre>topObject_perGroup()</pre>
Element-wise	_	element_perDP()	element_perGroup()

 $\mathsf{DP} = \mathsf{Data}\;\mathsf{Product}$

Parallel Optimizations

Write Optimization: Multi-Threaded Chunking

Parallel Chunking Divide events into thread-specific ranges for concurrent filling.

```
std::vector<unsigned int> seeds = generateSeeds(nThreads);
for (int th = 0; th < nThreads; ++th) {
  int first = th * chunkSize;
  int last = std::min(first + chunkSize, totalEvents);
  futures.emplace_back(std::async(
  std::launch::async, thinWorkFunc, first, last, seeds[th], th ));}</pre>
```

Example: executeInParallel writers.

Project Use: Scales writes with cores for large datasets.

Read Optimization: Cluster-Aware Splitting

Cluster Splitting Split read ranges by cluster boundaries to avoid duplicates.

```
auto clusters = split_range_by_clusters(*reader, nChunks);
for (auto& chunk : clusters) {
  futures.push_back(std::async(
   &processChunk, chunk.first, chunk.second
  ));
}
```

Helper Function Defines cluster-based splits.

```
std::vector<std::pair<size_t, size_t>>
split_range_by_clusters(ROOT::RNTupleReader& reader, int nChunks)
```

Project Use: Enhances read efficiency by reducing redundant reads.

Challenges

Parallel Write Challenge: File Corruption Solution

Problem: Concurrent Flushes

Unsynchronized cluster flushes cause file corruption in multi-threaded writes. **Example Issue**: Threads overwriting shared file regions.

Solution: Mutex Synchronization Lock during

flushes to serialize access per cluster.

```
for (int idx = first; idx < last; ++idx) {
   // Generate data for hits/wires
   if (hitStatus.ShouldFlushCluster()) {
    hitContext.FlushColumns();
   { std::lock_guard<std::mutex> lock(mutex); }
   hitContext.FlushCluster();
   }
}
```

Project Use: Ensures thread-safe parallel writes without corruption.

ROI Flattening vs. Custom Dictionary

ROI Flattening (Non-Dictionary)

Flattens hierarchical ROI data into vectors for efficient storage without custom classes.

```
struct Wires {
vector<unsigned int> fSignalROI_nROIs;
vector<size_t> fSignalROI_offsets;
vector<float> fSignalROI_data;
};
```

Example: Used in non-dictionary experiments for raw vector-based I/O.

Custom Dictionary (ROOT Classes)

Uses structured classes with ClassDef for ROOT's dictionary system, enabling object-oriented I/O.

```
struct RegionOfInterest {
size_t offset;
vector<float> data;
ClassDef(RegionOfInterest, 3)
};
```

Example: Used in dictionary experiments for type-safe, hierarchical data handling.

Results

Evaluation Metrics

- Write Throughput: Total events per second during RNTuple serialization.
- Cold Read Time: Latency for first access after file creation, reflecting raw I/O.
- Warm Read Time: Latency when data is cached, measuring memory locality effects.
- Compressed File Size: Total on-disk footprint post-write, accounting for RNTuple's column-wise compression.
- Multi-thread Scaling: Performance variation from 1 to 64 threads for write and read workloads.

AOS: Write Performance

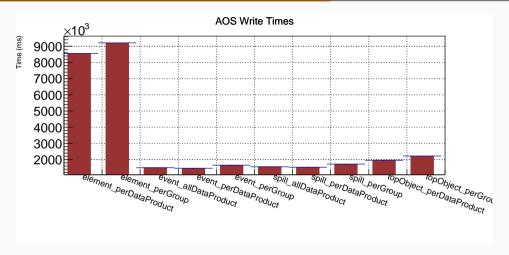

Figure 11: AOS (Array of Structures) Write Performance across different data organization strategies.

SOA: Write Performance

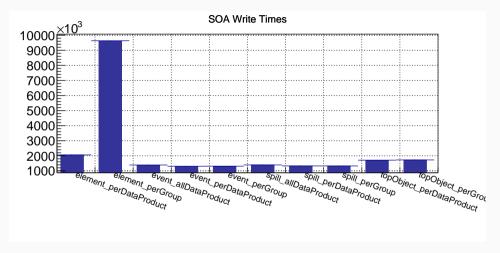

Figure 12: SOA (Structure of Arrays) Write Performance across different data organization strategies.

CPU Time Overheads

Writer	Α	В	С
event_perGroup	\checkmark	\checkmark	
${\tt spill_perGroup}$	\checkmark	\checkmark	\checkmark
$element_perData$	\checkmark	\checkmark	
$\verb"topObject_perData"$		\checkmark	
event_perData		\checkmark	
$spill_perData$		\checkmark	\checkmark

- A ROI flattening: dominant for *element* and *perGroup* writers.
- B Multiple NTuples: extra Fill/Flush cycles & mutex contention.
- C Spill re-partitioning: additional work unique to *spill* writers.

AOS vs SOA: Cold Read Performance Comparison

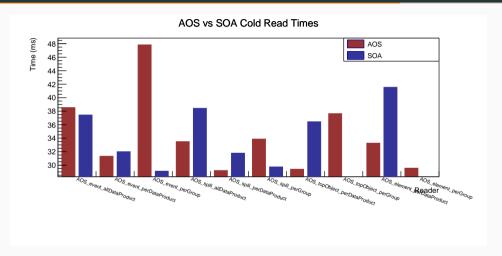

Figure 13: Cold Read Performance Comparison: Initial read times for AOS vs SOA implementations.

AOS vs SOA: Warm Read Performance Comparison

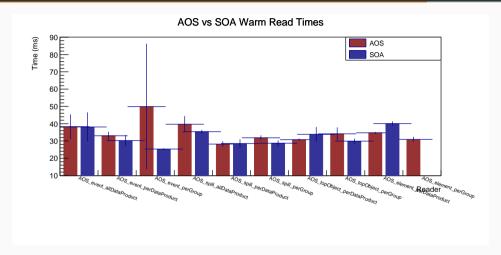

Figure 14: Warm Read Performance Comparison: Subsequent read times for AOS vs SOA implementations.

AOS: File Size Analysis

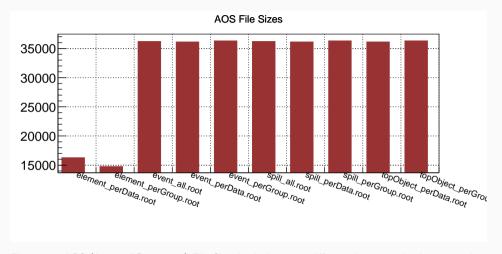

Figure 15: AOS (Array of Structures) File Size Analysis across different data organization strategies.

SOA: File Size Analysis

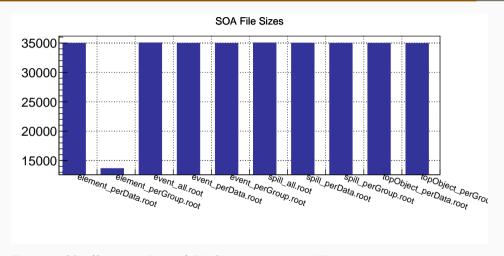

Figure 16: SOA (Structure of Arrays) File Size Analysis across different data organization strategies.

File Size Insights

Writer variant	Size (% of most)
aos_element_perData.root	47%
${\tt soa_element_perData.root}$	100%
aos_element_perGroup.root	42%
soa_element_perGroup.root	39%
aos_event_* / aos_spill_*	\sim 103%
soa_event_* / soa_spill_*	100%

Key Take-aways

- Deep nesting & high row counts double basket overhead (offset tables, headers, CRC).
- Flattened perGroup writers cut size roughly in half by removing ROI nesting.
